Background

The population of adults with congenital heart disease is increasing and is estimated to grow at a rate of 6% per year in developed countries. In the United States alone, it is estimated that there are approximately 1.4 million people suffering from this condition, compared to one million patients under 18 with congenital heart disease.

This can be explained by the availability of better and more timely diagnostic methods, especially in prenatal diagnosis with fetal echo, optimal surgical and interventional results, successful specialized cardiovascular intensive care and the experience of high-volume reference centers that provide comprehensive management with lower postoperative mortality, which leads to greater survival in the medium and long term. In general, with these measures, 85% of patients with congenital heart disease are expected to reach adulthood^{1,2}.

In the world life expectancy at birth has improved, and in Colombia today it is 73.95 years in the general population; 70.95 for men and 77.10 for women, a factor that favors adults with heart disease, since they are influenced by this general change³.

A study carried out in Quebec shows how in two different periods, one from 1987 to 1988 compared to the period between 2004 and 2005 there is a large change in the

mortality of children with congenital heart disease. In the first period, mortality during the first year of life was 25%, compared to the general population in which it was less than 1%. Subsequently, in the second period studied from 2004 to 2005, this mortality decreased especially in the first year, and became very similar to that of the general population, a fact that supports the hypothesis of why this population reaches adulthood in a very high percentage⁴.

The Warnes et al. study reported how the possibility of survival to adulthood after surgery has changed since the 1950s when it was only 25%, to 90% by 2010⁵ (fig. 1).

Severity of disease and causes of mortality

Congenital heart diseases have different degrees of severity independently of the scale to determine surgical risk (RACHS-1 or STAT) ^{6,7}. Some authors classify them as simple, moderate and severe.

The simple ones include: simple interventricular communication, bicuspid aortic valve without lesion, simple mitral lesion, *ductus arteriosus* and mild pulmonary stenosis. This group corresponds to 47% of cardiopathies. The second or moderate group (which represents 38%) includes heart diseases such as tetralogy of Fallot, complex defects of the interventricular *septum*, Partial anomalous venous drainage, partial AV canal, coartation of the aorta, Ebstein's anomaly and pulmonary stenosis, among others. The third group correspond to 15% and include severe defects some more serious such mitral atresia, transposition of great arteries, corrected transposition, heterotaxia syndromes, double outlet right or left ventricle *truncus arteriosus*,

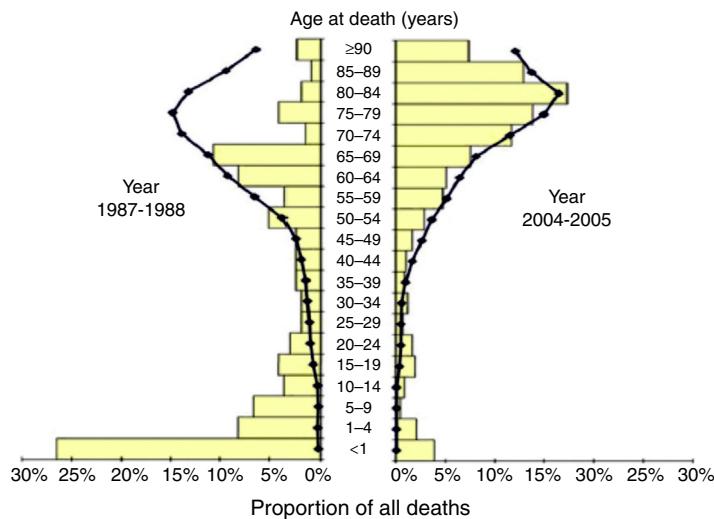

Figure 1 Distribution of age at Death in patients with Congenital heart diseases in 1987 to 1988 and 2004 to 2005. Source: Khairy et al. Changing mortality in congenital heart disease. JACC. 2010;56:1149–57.

In this study two different periods from 1987 to 1988 compared to the period between 2004 and 2005, are shown, where the change in mortality risk is observed especially during the first year of life vs. the general population.

single ventricle and cyanotic lesions, as well as Eisenmenger syndrome.^{8,9}

The most important of this classification is that it includes the prognostic dimension. 50% of the patients in the moderate and severe groups will require a reoperation and a large number will have other complications such arrhythmias of difficult management, heart failure, pulmonary hypertension, etc.

Mortality increases to a mean age of 48.8 years, in which case this mortality is due to cardiovascular disease in 77% and 45% of these to heart failure.¹⁰ Likewise, according to the severity of the disease, the most complex ones will die earlier, including patients with Fontan circulation, complex heart disease, Eisenmenger's syndrome, univentricular heart with right-sided systemic ventricle, and Ebstein's anomaly.⁹

Other studies show that the main causes of morbidity and mortality are heart failure in 28% and non-cardiovascular causes in 23%, such as malignancy, pneumonia, liver failure, endocarditis and renal failure. 19% have sudden death, 18%, other cardiac alterations such as coronary disease, diabetes, hypertension, obesity and stress, and 14% vascular events, such as cerebral aneurysm and aortic aneurysm.¹⁰

Presence of pulmonary hypertension affects up to 6% of patients and has a very important impact on survival.¹¹

Neurological and psychological injuries

The presence of old neurological lesions and new events associated with metabolic alterations, significantly affect the independence of these patients. Likewise, it is predicted that up to 30% of these patients have psychological and psychiatric disorders, secondary to repetitive

trauma, old experiences, as well as posttraumatic stress disorders.¹²

Contraception and reproduction

Contraception and counseling are very important as the incidence of children of these patients with congenital heart diseases is higher than that of the normal population; however, many of these patients have children and their mothers, specifically those with Eisenmenger Syndrome, Fontan surgery and cyanotic diseases may be at increased risk of complications such as arrhythmia, heart failure and cardiovascular events especially during pregnancy.¹³

Prevalence of congenital heart disease in Colombia

The prevalence of patients with congenital heart disease has stabilized in the world, and in Colombia, concretely it is of 9 / 1,000 live births.^{14,15} In the country according to DANE figures, 645,550 children are born each year, (year 2015)³ and with a prevalence of 9.1 / 1,000 live births it is assumed that 5,805 new children are born with congenital heart disease every year. Of these new patients, 70% (4,063 patients) require surgical or interventional treatment during the first year of life because the mortality without any treatment is high, almost 50%. Unfortunately, only about 2,349 are intervened with surgery and 1,600 with interventional procedures (total of 3,949). Of these only 1,500 out of a total of 4,063 children under one year of age have an opportunity for medical management remaining approximately 2,500 new children without it and high mortality risk in this first year.¹⁶

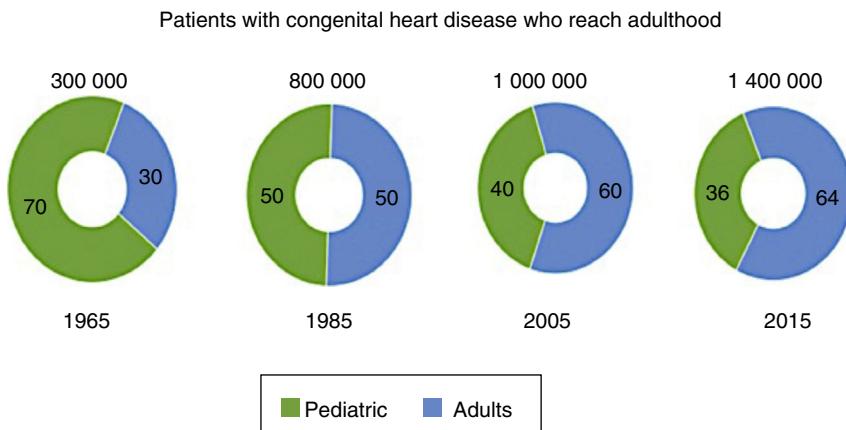

Figure 2 Patients with congenital heart disease who reach adulthood

Relationship between adults and patients under 18 years with congenital heart disease through the years since the mid 1960s when adults only accounted for 30% and 2015 when it is estimated to be 64%. Williams et al. J Am coll cardiol 2006, Gilboa S circulation. 216; 134:101-109

Prevalence of adults with congenital heart disease

As mentioned above, the percentage of patients with congenital heart disease receiving treatment and surviving has improved significantly in the world and in Colombia, so a greater number of these patients reach adulthood. Another large number of individuals with less complex diseases will survive to adulthood and will only receive treatment after the age of 18.

Prevalence studies for adults with congenital heart disease have been done as a systematic review and based on evidence calculations suggesting that the prevalence of adults with congenital heart disease in specific regions may be 3,000 per million inhabitants, ranging from 2,297 to 3,532 or 4.09 adults with congenital heart disease per 1,000 adults, according to epidemiological approaches based on Quebec population studies^{17,18}. According to these approximations, it is estimated that the relationship between adults and children under 18 years of age with congenital heart disease has been reversed since the mid-60s, when adults only represented 30% and by 2015 would be greater than 64%² (fig. 2).

Adults with congenital heart disease in Colombia

According to the approaches mentioned and if coverage and survival of newborns were similar to those of developed countries, in Colombia there would be 141,000 adults with congenital heart disease. However, due to deficiencies in early care of the newborn and deficiencies of the system, it is assumed that due to lack of efficiency in 60% of cases, only 40% will arrive to adulthood. We could speculate that we would only have approximately 46,000 adult patients with congenital heart disease.

History and impact on treatment

Cardiac surgery began in the early 1940s and 1950s with the ligation of the *ductus arteriosus* by Gross in Boston, the Blalock-Taussig shunt at John Hopkins Hospital in 1945, the repair of coarctation of the aorta in 1944 in Sweden by Crafford, and a large number of closed procedures. However, with the appearance of extracorporeal circulation introduced by Lillehey, Gibbon and Kirklin in the United States in the mid-1950s, a spectacular development was observed in intracardiac repair, which after the 1980s was successfully applied in the newborn and in the first months of age, changing the prognosis and survival of these patients.

Colombia, like Latin America, with the leadership of surgeons and cardiologists, was not an exception to this development and in 1948 the first *ductus arteriosus* closure was made; in 1952 Rueda performed possibly the first repair of aortic coarctation and later a group of national leaders in Bogotá and Medellin began intracardiac surgery using moderate surface hypothermia and cardiac arrest and later with the use of extracorporeal circulation, always supported by international pioneers such as Walton Lillehey, Melrose and Humprey, who visited Colombia and helped develop the different strategies of the moment.

Similarly, thanks to these pioneers and their disciples, schools and centers specialized in cardiovascular surgery were created, as well as training programs of this specialty, and for this reason, today patients with congenital heart disease in Colombia are more likely to survive and reach adulthood age¹⁹.

Congenital heart disease centers for children and adults

The main objectives for the care of these patients are based in the following factors:

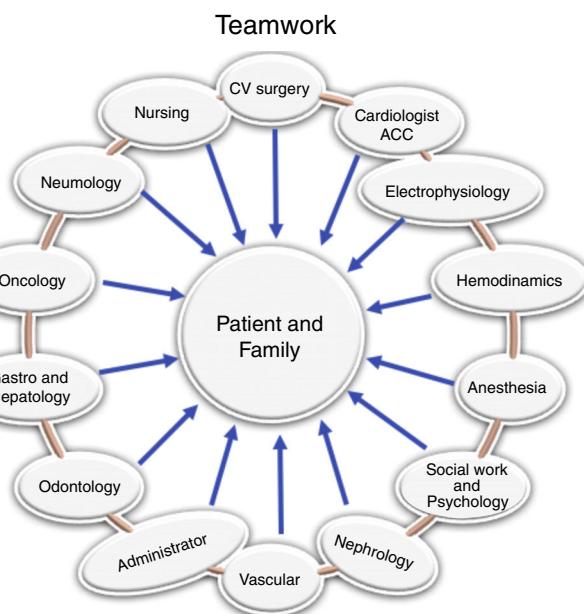

Figure 3 Congenital Heart Disease Center
Multidisciplinary group that must assume the integrated management of a center of adults with congenital heart disease.

1. The importance of maintaining care throughout their life.
2. The transfer of patients between their pediatric physicians to adult cardiologists with the least loss of follow-up.
3. The transition is a very important factor that includes a process of maturation in which the patient gains self-management and achieves to create some independence from the care of his family. Others unfortunately do not succeed because of neurodevelopmental difficulties or psychosocial alterations secondary to the treatment process and its possible complications and comorbidities that they develop during their life.

Due to the constant growth of this population, centers specialized in congenital heart disease in adults have been created. These must include not only a specialist in adult congenital heart disease, but a multidisciplinary group for follow-up and management (fig. 3). Refer centers in general see between 2,500 and 3,000 patients per year and it is suggested that one center be created for every 2,850 patients, a fact that based on the projection of the number of adults with congenital heart disease in Colombia would merit having at least three specialized centers in this population.

The Cardioinfantil Foundation - Institute of Cardiology is a refer center in Colombia and Latin America. From 2005 to 2016, a total of 444 adults with congenital heart defects have been surgically intervened, most of them due to interatrial and interventricular defects, followed by reoperations in patients with previous repair of Tetralogy of Fallot, and partial venous drainage. Mortality in this group is low of 1.6%, but the presence of arrhythmias is the most common in the postoperative period. Follow-up shows a survival of 97% (CI 95% 84-97) at 10 years²⁰.

Conclusion

The prevalence of adults with congenital heart disease is increasing and this population will be one of the great challenges of cardiology and cardiac surgery in the future.

It is critical to anticipate the changes of these patients over time and their comorbidities to minimize long-term complications.

The creation of centers of reference will be essential for proper management, transition and transference to guarantee a transitional and non-traumatic process for the patient and his family. In this sense, the work of a multidisciplinary team is crucial.
